Abstract - parallel computing targets problems that are scalable and possibly distributed, dividing the problem into smaller pieces. This approach may be explored to satisfy real time constraints required by augmented reality algorithms. The implementation is able to provide satisfactory speed up improvements using CUDA, NVIDIA's architecture for GPU programming. The aim of this paper is not to present a new technology, but to show the great improvements that can be obtained by applying it in computer vision and augmented reality applications. The MP-KDD algorithm largely reduces the computational overhead by removing all floating-point and multiplication operations while preserving the currently popular SIFT and SURF algorithm essence. The MP-KDD algorithm can be directly and effectively mapped onto the pixel-parallel and row-parallel array processors of the vision chip. The vision chip architecture is also enhanced to realize direct memory access (DMA) and random access to array processors so that the MP-KDD algorithm can be executed more effectively.

Index Terms - Image retrieval, Object segmentation, Object recognition, Image Databases, Computer Vision.

INTRODUCTION

The digital processors each rasterized by an important versatility and their easy programming. However, in our approach, an Ewan log processing architecture has been designed. It high lights a compromise between versatility, parallelism, processing speeds and resolution. The analog processing operators are fully programmable devices by dynamic reconfiguration; they can be viewed as a Software-programmable image processor dedicated to low-level image processing. The main objective will be to design a pixel of less than 10m, 10 mw it has fill factor of 20%. Thus, with the increasing scaling of the transistor sin such technology, we could consider the implementation of more sophisticated image processing operators dedicated to face localization and recognition. Other application-specific services such as those in Earth and Environmental science can be expected to become clearer as projects in these areas mature, is dominated by the needs of the particle physics community and here one finds the greatest overlap with existing European and US efforts. Campus (computing) Grids can also be expected to grow in importance. Replica management, access to storage, scheduling and virtual data are major compute/file Grid areas. The scale of the particle physics problem emphasizes the need for robust well-managed grids. The SIMD Peer ray can efficiently finish low-level pixel-parallel operations, but it is hard to perform row-parallel and non-parallel operations. Recently, multi-SIMD vision processor architecture was proposed, and its FPGA implementation demonstrated the potential advantage of integrating different levels of parallel processors into one chip. Second, previous reported vision chips have one PE along with one pixel, but the PE’s area is 5–20 times larger than the sensor pixel’s area. Since the chip area grows quickly with image size, the image that the chip captured has limited size. Moreover, this fixed one-to-one PE-pixel mapping relationship reduces the image processing flexibly. The amount of result data obtained by the parallel processors is much smaller than the raw image, and can be fetched by the MPU through data bus. The MPU runs high-level algorithms and adjust the sensor parameters on demand. The instructions for the PE array and the RP array are stored in an on chip program memory and are issued by a specific controller, whose operation is controlled by the MPU. In this way, the parallel processors can directly access its program memory, and the parallel processors can operate in parallel with the MPU. To achieve higher vision chip performance with the key point framework, this paper proposes a novel massively parallel key point detection and description (MP-KDD) algorithm based on the combination of MP-SIFT detector and MP-SURF descriptor. The MP-KDD algorithm largely reduces computational costs by removing all floating-point and multiplication operations while preserving original SIFT and SURF algorithm essence. The MP-SIFT detector and the MP-SURF descriptor in the algorithm can be directly and effectively mapped onto the pixel-parallel and row-parallel array processors of the vision chip. About 600–760 fps of processing speed can be achieved. To perform the algorithm more effectively, we also propose enhanced vision chip architecture with support for direct memory access (DMA) and random access to array processors. The rest of this paper proceeds as follows. The proposed vision chip architecture is briefly described. In, after an overview of the original SIFT and SURF algorithms, the proposed MP-KDD algorithm is illustrated in detail. The experimental results of the MP-KDD algorithm on a FPGA-based prototype. And finally, One of the applications is target counting. This application n counts the e cumulative number of targets coming in to sight. This can also count only desired targets. At a frame rate of 0.5 kHz, we found experimentally that the
maximun target speed was 20km/h. This counting technique could be applied, for example, to high-speed in section of small creatures and crops. Another possible application is the measurement of high-speed rotation. In this application, the rotation axis and rotation speed of a ball are measured in real-time. As a result of experiments at 1 kHz frame rate, the maximum rotation speed of the object was 1200rpm. We believe that such rotation measurement could find applications in ball games, such as soccer and baseball. A fast random access to their neighborhood is compulsory in high-speed feature extraction. In our chip architecture, one RP can randomly access (only read) any PE in the same row by column index addressing. Likewise, the MPU and DMA controller can randomly access (read and write) any RP by row index addressing. To further enhance the random access ability, a technique called Delegated access is proposed in this paper.

EXISTING SYSTEM

In previous segmentation methods, the process applies only for segmenting an object and that too only for single object. Most of the methods apply only for binary or gray images. In existing retrieval systems, various algorithms proposed to improve the retrieval properties between two images. They are such as BoW (Bag of words), GIST detectors, MSER detectors, GMM and SIFT are used to extract the feature. Among this, mixture models are commonly used in all detectors. Each model improves at least any of the parameter which improves the matching property. Pixels from the segmented object is known as feature pixels. Depending on features of pixels, the pixel matching performed between multiple images and then the image retrieved. The data sets used are commonly availed Real world datasets such as Oxford buildings and INRIA holidays. A Maximally Stable Extremal Region (MSER) is a connected component of an appropriately thresholded image. The word ‘extremal’ refers to the property that all pixels inside the MSER have either higher (bright extremal regions) or lower (dark extremal regions) intensity than all the pixels on its outer boundary. The ‘maximally stable’ in MSER describes the property optimized in the threshold selection process. The set of extremal regions i.e., the set of all connected components obtained by threshold holding, has a number of desirable properties. Firstly, a monotonic change of image intensities leaves Unaffected, even if the camera is non-linear (gamma corrected). Secondly, continuous geometric transformations preserve topology—pixels from a single connected component are transformed to a single connected component.

DISADVANTAGES.

- Here the image can be described as the histogram which is used to compute a similarity between the pair of images.
- By using K-mean clustering algorithm the vocabularies are build. But its results usually scale poorly with the size of the vocabulary.

LITERATURE SURVEY

"A CMOS Imager With a Programmable Bit-Serial Column-Parallel SIMD/MIMD Processor". Author Name:- Hirofumi Yamashita, and Charles G. Sodini, The processor is physically arranged as a densely packed 2-D processing element (PE) array at an imager column level. The digital processor has a multiple-instruction–multiple-data (MIMD) architecture configured multiple column-parallel single-instruction–multiple-data (SIMD) processors. The prototype imager chip with 128×128 pixels and 4×128 PE array designed with 0.6-µm technology was fabricated, and its functionality was tested. The estimation of performance level of the proposed processor architecture with an advanced technology such as the 0.09-µm process technology shows that the proposed imager chip architecture has a potential of giga sum operations per second per square millimeter class processing performance. The proposed image processing architecture uses the system partitioning approach, where computationally intensive pixel-rate processing alone is implemented on an imager chip to target low-level image processing tasks. The processor is physically arranged as a densely packed 2-D processing element (PE) array at an imager column level. The digital processor has a multiple-instruction–multiple-data (MIMD) architecture configured multiple column-parallel single-instruction–multiple-data (SIMD) processors. The fully programmable image processor incorporated in an imager chip is advantageous over the alternative special-purpose on-imagedigital signal processor (DSP) solutions because of its flexibility for an image processing algorithms. The layout pitch of all the datapaths is matched to the pixel column pitch in order to minimize silicon area. Image data flow from the pixel array to the output register along the column direction; thus, no extra wiring for long-distance data transfer is required. The proposed dense array of column-parallel data path architecture realizes high computational power with a minimal silicon area. The performance level of the proposed processing architecture with advanced process technology shows that the proposed imager chip architecture is one of the candidates for an imager with a fully programmable high-speed processing performance for a variety of consumer imaging applications. The aspect of the imager chip implementing the proposed SIMD/MIMD processor is shown in As described in Section IV, by employing the proposed processing scheme, the total processor silicon area becomes scalable with an increasing number of pixels. The ratio of the processor silicon area to the pixel-array silicon area remains as the number of pixels increases, if the processing task is the same.

The advantage of column-parallel processing architecture is compared to three types of on-imager parallel processor architecture. The advantage of a bit-serial architecture is its reduced hardware complexity.

**Disadvantage:**

The bit-parallel processor architecture used in the previous work makes it difficult to implement a per-column PE array structure since a multibit bus architecture covers considerable PE column pitch.

"Parallel Hardware Architecture for Scale and Rotation Invariant Feature Detection".

**Disadvantage:**

The block structure of the Gaussian kernel symmetry and save two multipliers by reusing data from the multiplication result at k1 and k2.

One advantage of this dependency is the possibility of having a module slower than the period between two pixels, since this difference can be compensated when a pixel is rejected by some previous function.

**Disadvantage:**

Our application is not considered a negative result since the proportion between false positive and true matching has stayed approximately the same.

**PROPOSED SYSTEM**

Our work proposes a novel model that concurrently tackles the problems of image segmentation (ROI segmentation) and Retrieval. This kind of retrieval after segmentation provides matching accuracy between images. This paper studies the application of the Adaptive Neuro-Fuzzy Inference System (ANFIS) for segmentation of images (oxford building dataset). Probabilistic generative model is used for the problem of image retrieval based on MP-KDD detectors. The proposed method has the ability to work more than one ROI in the query image. The fuzzy inference system that we have considered is a model that maps–input characteristics to output membership functions, input membership function to rules a set of output characteristics to output membership functions, and the function to a single-valued output, or a decision associated with the output. A network-type structure similar to that of a neural network, which maps inputs through input membership functions and associated parameters, and then through output membership functions and associated parameters to outputs, can be used to interpret the input/output map. The parameters associated with the membership functions will change through the learning process. The computation of these parameters (or their adjustment) is facilitated by a gradient vector, which provides a measure of how well the fuzzy inference system is modeling the input/output data for a given set of parameters. Once the gradient vector is obtained, any of several optimization routines could be applied in order to adjust the parameters so as to reduce some error measure (usually defined by the sum of the squared difference between actual and desired outputs). Anfis uses either back propagation or a combination of least squares estimation and back propagation for membership function parameter estimation. When checking data is presented to anfis, as well as training data, the FIS model is selected to have parameters associated with the minimum checking data model error. One problem with model validation for models constructed using adaptive techniques is selecting a data set that is both representative of the data and can be trained. The trained model is intended to emulate, yet sufficiently different from the training data set so as not to render the validation process trivial. If you have collected a large amount of data, hopefully this data contains all the necessary representative features, so the process of selecting a data set for checking or testing purposes is made easier.
ADVANTAGES:-
• The pixel similarity detection can improve than the previous designs.
• Hence the effectiveness of ROI segmentation and retrieval, can improve the matching property.
• This comparison determines that our work can offer better accuracy and higher frame rate within much less hardware assets than the state-of-the-art vision chip in complex tenders.

METHODOLOGY
SOFTWARE ARCHITECTURE

IMPLEMTATION

MODULES DESCRIPTION

Pre processing – Filtering – Median filter :
Initially the input images are preprocessed in order to improve the quality of the images we normally employ some filtering operations. Median filter is used for filtering. The median filter considers each pixel in the image in turn and looks at its nearby neighbors to decide whether or not it is representative of its surroundings. Instead of simply replacing the pixel value with the median of neighboring pixel values. The median is calculated by first sorting all the pixel values from the surrounding neighborhood into numerical order and then replacing the pixel being considered with the middle pixel value.

ROI segmentation – ANFIS:-
Adaptive Neuro-Fuzzy system is a kind of artificial neural network ANFIS used for automatic multilevel image segmentation. This system consists of multilayer perceptron (MLP) like network that performs color image segmentation using multilevel thresholding. Threshold values for detecting clusters are found automatically using Fuzzy C-means (FCM) clustering technique. Neural network is employed to find the number of objects automatically from an image. A class of adaptive networks that are functionally equivalent to fuzzy inferencensystems ANFIS architectures representing both the Sugeno and Tsukamoto fuzzy models. ANFIS system uses two neural network and fuzzy logic approaches. When these two systems are combined, they may qualitatively and quantitatively achieve an appropriate result that will include either fuzzy intellect or calculative abilities of neural network. As other fuzzy systems, the ANFIS structure is organized of two introductory and concluding parts which are linked together by a set of rules. We may recognize five distinct layers in the structure of ANFIS network which makes it as a multi-layer network. A kind of this network, which is a Sugenotype fuzzy system with two inputs and one output.

Object Retrieval – MPKDD:-
A massively parallel key point detection and description. The MP-KDD algorithm largely reduces the computational overhead by removing all floating-point and multiplication operations while preserving the currently popular SIFT and SURF algorithm essence. We can freely choose any combination of detector and descriptor from the SIFT and SURF algorithms. Massively parallel key point detection and description (MP-KDD) algorithm is based on the combination of MP-SIFT detector and MP-SURF descriptor. To validate ORB, we perform experiments that test the properties of ORB relative to SIFT and SURF, for both raw matching ability, and performance in image-matching applications. We also illustrate the efficiency of ORB by implementing a patch-tracking application on a smartphone. An additional benefit of ORB is that it is free from the licensing restrictions of SIFT and SURF.

RESULT

Fig -1 Image for ROI segmentation

Select image from Database1

Fig -2 Seed selection

First it needs to find regions of interest on the basis of the brightest pixels having the maximal values because they represent the most significant regions in the image. Once the regions of interest are determined, the centroid of each region needs to found. The resulting centroid pixel is the seeds for region growing algorithm.
Fig -3 Segmented ROI

By using fuzzy rule Segmented ROI is generated.

Fig -4 Select image for Retrieval

Select image from Database2

Fig -5 Retrieval

Results of the matching process between a query image and two images of the reference database. As can be observed, the thresholds used were very conservative so that either correctly (left) or wrongly (right) retrieved images exhibited a relevant number of potential matches. Subsequently, the proposed generative model is in charge of filtering out false matches and providing a refined image ranking.

SOFTWARE DESCRIPTION

MATLAB® is a high-level technical computing language and interactive environment for algorithm development, data visualization, data analysis, and numerical computation. Using MATLAB, you can solve technical computing problems faster than with traditional programming languages, such as C, C++, and FORTRAN. MATLAB is a data analysis and visualization tool which has been designed with powerful support for matrices and matrix operations. As well as this, MATLAB has excellent graphics capabilities, and its own powerful programming language. One of the reasons that MATLAB has become such an important tool is through the use of sets of MATLAB programs designed to support a particular task. These sets of programs are called toolboxes, and the particular toolbox of interest to us is the image processing toolbox. Rather than give a description of all of MATLAB's capabilities, we shall restrict ourselves to just those aspects concerned with handling of images. We shall introduce functions, commands and techniques as required.

A MATLAB function is a keyword which accepts various parameters, and produces some sort of output: for example a matrix, a string, a graph. Examples of such functions are sin, I'm read, and I'm close. There are many functions in MATLAB, and as we shall see, it is very easy (and sometimes necessary) to write our own. MATLAB's standard data type is
the matrix all data are considered to be matrices of some sort. Images, of course, are matrices whose elements are the grey values (or possibly the RGB values) of its pixels. Single values are considered by Mat lab to be matrices, while a string is merely a matrix of characters; being the string's length. In this chapter we will look at the more generic Mat lab commands, and discuss images in further chapters. When you start up Mat lab, you have a blank window called the Command Window, in which you enter commands. Given the vast number of Mat lab's functions, and the different parameters they can take, a command line style interface is in fact much more efficient than a complex sequence of pull-down menus. You can use Mat lab in a wide range of applications, including signal and image processing, communications, control design, test and measurement, financial modeling and analysis. Add-on toolboxes (collections of special-purpose Mat lab functions) extend the Mat lab environment to solve particular classes of problems in these application areas. Mat lab provides a number of features for documenting and sharing your work. You can integrate your Mat lab code with other languages and applications, and distribute your Mat lab algorithms and applications.

When working with images in Mat lab, there are many things to keep in mind such as loading an image, using the right format, saving the data as different data types, how to display an image, conversion between different image formats. Image Processing Toolbox provides a comprehensive set of reference-standard algorithms and graphical tools for image processing, analysis, visualization, and algorithm development. You can perform image enhancement, image de blurring, feature detection, noise reduction, image segmentation, spatial transformations, and image registration. Many functions in the toolbox are multithreaded to take advantage of multicore and multiprocessor computers.

Key Features
• High-level language for technical computing
• Development environment for managing code, files, and data
• Interactive tools for iterative exploration, design, and problem solving
• Mathematical functions for linear algebra, statistics, Fourier analysis, filtering, optimization, and numerical integration
• 2-D and 3-D graphics functions for visualizing data
• Tools for building custom graphical user interfaces
• Functions for integrating Mat lab based algorithms with external applications and languages, such as C, C++, Fortran, Java, COM, and Microsoft Excel.

**FUTURE SCOPE**
In this paper we have proposed a generative probabilistic model that concurrently tackles image retrieval and roi segmentation problems. By jointly modeling several properties of true matches, namely: objects undergoing a geometric transformation, typical spatial location of the region of interest, and visual similarity, our approach improves the reliability of detected true matches between any pair of images. Furthermore, the proposed method associates the true matches with any of the considered foreground components in the image and assigns the rest of the matches to a background region, what allows it to perform suitable roi segmentation. We have conducted a comprehensive assessment of the proposed model. Our results on two well-known databases, oxford building and holidays, prove that it is highly competitive in traditional image retrieval tasks, providing favorable results in comparison to most of the state-of-the-art systems. Regarding roi segmentation, assessed on the oxford database, the proposed model outperformed ransac, the most well-known geometric approach. In our opinion these results are due to two main reasons: first, our model jointly manages several properties of true matches; and second, by considering the whole set of reference images at once, the proposed method provides a robust method for estimating the actual geometric transformation undergone by the objects. In particular, by computing the posterior probability that a match is considered as true (e.g. It belongs to any of the considered foreground components), successfully rejects outliers in the estimation of the geometric transformation. This outlier rejection ability notably improves when all the reference images are jointly considered in comparison to traditional techniques where each pair of images (query and reference) is addressed independently. In addition, our model can also work in scenarios where there is more than one object-of-interest in the query image. To assess the performance of the proposed model, we have conducted three different experiments: a multi-class category segmentation experiment on the ethz toys dataset; a multi object detection experiment on the rgb-d dataset; and a multiview object retrieval experiment on the oxford building dataset. For the first two cases, we developed and tested a method for automatically selecting the number k of objects of-interest in the query image, with results very close to those ones achieved with the optimal k in each case. In the third experiment, the results showed a significant performance improvement when the number of foreground objects considered by the model fitted the actual number of objects-of-interest. These results allow us to conclude that the performance of the retrieval process can be notable improved when different views of the object-of-interest are available.

**CONCLUSION**
This paper proposes a scale-invariant keypoints detection and feature description algorithm named as MP-KDD for vision chips. The MP-KDD algorithm is inspired by the combination of the original SIFT detector and SURF descriptor, but involves only simple fixed-point operations without any multiplicationrequirement. The MP-KDD algorithm can be directly and efficiently mapped onto the massively parallelvision chip architecture. To be better compatible with the MP-KDD algorithm, this paper also
enhance the vision chip architecture with multiple levels of array random access.

The visual measurements based on multi-target tracking, target counting and rotation measurement. The experimental results using the vision chip we have developed show that both methods excel in the points, high-precision, high-frame-rate observation and flexibility. These visual measurements, providing such advantages, are expected to be applied in various fields, such as in spection, industrial ap-plications, sport measurement, robot control, and so on.
